Abstract All living organisms require accurate mechanisms to faithfully inherit their genetic material during cell division. The centromere is a unique locus on each chromosome that supports a multiprotein structure called the kinetochore. During mitosis, the kinetochore is responsible for connecting chromosomes to spindle microtubules, allowing faithful segregation of the duplicated genome. In most organisms, centromere position and function is not defined by the local DNA sequence context but rather by an epigenetic chromatin-based mechanism. Centromere protein A (CENP-A) is central to this process, as chromatin assembled from this histone H3 variant is essential for assembly of the centromere complex, as well as for its epigenetic maintenance. As a major determinant of centromere function, CENP-A assembly requires tight control, both in its specificity for the centromere and in timing of assembly. In the last few years, there have been several new insights into the molecular mechanism that allow this process to occur. We will review these here and discuss the general implications of the mechanism of cell cycle coupling of centromere inheritance.

Keywords Centromere · CENP-A · cell-cycle · Cdk · cyclin · CCAN

Abbreviations

APC/C	Anaphase-promoting complex/cylosome
CCAN	Constitutive centromere-associated network
CHD1	Chromodomain-helicase-DNA-binding protein 1
Cdk	Cyclin-dependent kinase
CENH3	Centromeric histone H3
CENP	Centromere protein
CID	Centromere identifier
Cse4	Chromosome segregation 4
FACT	Facilitates chromatin transcription
HCP-3	HoloCentric chromosome binding Protein-3
HJURP	Holliday junction recognizing protein
KNL2	Kinetochore-null 2
MgcRacGAP	Male germ cell Rac GTPase-activating protein
Mis	Minichromosome instability
Mis18BP1	Mis18 binding protein 1
RbAp	Retinoblastoma protein associated protein
RSF	Remodeling and spacing factor
S2	Schneider 2
SCF	Skp1 Cullin, F-box protein
Scm3	Suppressor of chromosome missegregation 3
TSA	Trichostatin A

Introduction

Cell division requires the coordinate action of mechanisms that duplicate the full complement of the genome and subsequently partition these copies among newly formed daughter cells. Key to the latter process of chromosome segregation is a chromosomal region called the centromere. This region, initially defined cytologically as the primary constriction on metazoan metaphase chromosomes, is the site of assembly of a large complex of proteins that function in tethering sister chromatids together as well as in generating attachments to spindle microtubules in a bipolar fashion (Fig. 1). Microtubule binding is mediated by the kinetochore, a complex of proteins that is assembled onto the centromere complex during mitosis.

Fig. 1 The centromere, a chromatin locus essential for chromosome segregation. Schematic representation of a metazoan monocentric centromere. Centromeres are nucleoprotein complexes that form on a single locus on each chromosome and form the attachment site for spindle microtubules. Centromeric chromatin is distinguished from general chromatin by the presence of CENP-A containing nucleosomes, which are interspersed with histone H3 nucleosomes. CENP-A chromatin is the site of assembly of the constitutive centromere-associated network (CCAN), which in turn nucleates the kinetochore, a group of proteins with microtubule binding activity and proteins required for mitotic checkpoint signaling. This complex organization allows for proper chromosome segregation by ensuring bipolar attachment of the two sister chromatids during metaphase and drives separation of sisters during anaphase

Centromeres are propagated largely independently of *cis*-acting DNA sequences indicating they are maintained through an epigenetic mechanism. We will discuss recent evidence implicating the unique chromatin structure that is generated by the histone H3 variant CENP-A (centromere protein A) in epigenetic maintenance of centromeres. In addition, we will discuss work in both fly and human cells that has shed light on the temporal dynamics of CENP-A chromatin. Determining how centromeric chromatin turns over across the cell division cycle is crucial to understand how CENP-A, as a key component of the epigenetic mechanism at centromeres, is itself inherited and duplicated. We will present recent findings and outline differences and commonalities among different organisms. Finally, we will discuss the consequences of the unique timing of centromeric chromatin assembly for maintenance of centromere function and architecture.

The role of DNA sequence in centromere specification

Contrary to what is observed in *Saccharomyces cerevisiae*, where a specific 125-bp sequence is sufficient for centromere formation, in most eukaryotes, the centromere typically forms on a subset of long arrays of repetitive DNA. In humans, such DNA regions are comprised of repetitive arrays of 171-bp sequences called α -satellites (or alphoid DNA), that can span several megabases (Schueler and Sullivan 2006). One of the first centromeric proteins described, Centromere Protein B (CENP-B) was found to bind specifically to those repeats suggesting that this DNA sequence is important for centromere function (Masumoto et al. 1989). While maintenance of pre-existing centromeres appears largely independent of the underlying DNA sequence (discussed below), centromeric DNA is essential for generating centromeres de novo, both in fission yeast and human cells (Takahashi et al. 1992; Harrington et al. 1997). In human cells, it was further shown that both alphoid DNA and the presence of CENP-B binding sites are important for de novo centromere formation (Ohzeki et al. 2002). However, apart from the mammalian CENP-B box, identifying what sequence features of centromeric DNA are important for centromere formation has been challenging, principally because the highly repetitive tandem sequence repeats present in metazoan centromeres are not conserved among species or, in the case of, e.g., human centromeres, even among different chromosomes of an individual organism (Willard 1991).

This suggests that the role of DNA sequences at the centromere is to provide a structural context rather than a specific sequence motif.

The epigenetic inheritance of centromeres

Despite its requirement for centromere establishment, there is little support for a prominent role of centromeric DNA in the maintenance of existing centromeres. Evidence against such role came initially from the characterization of stably transmitted dicentric chromosomes in humans and flies. Two active centromeres on a single chromosome may be deleterious to the cell, leading to chromosome breakage and loss. However, dicentric chromosomes can be inherited by inactivating one of the centromeres, without changing its DNA sequence (Earnshaw and Migeon 1985), in a process that is still poorly understood. This indicates that canonical centromere sequences are not sufficient for centromere function. In addition to insufficiency, several lines of evidence have demonstrated that centromeric DNA is also not necessary for the maintenance of centromeres. While CENP-B binding sites are critical for de novo formation of centromeres, the CENP-B protein is non-essential in mice, indicating that as long as preassembled centromeres are inherited, CENP-B binding to centromeres is not required (Hudson et al. 1998; Kapoor et al. 1998; Perez-Castro et al. 1998).

The most direct evidence demonstrating centromere maintenance in the absence of specific DNA sequence elements in cis was provided by the discovery of human neocentromeres which are formed in genomic regions lacking any characteristic centromeric DNA sequences (Voullaire et al. 1993). At such neocentromeres, all essential centromere and kinetochore proteins tested thus far (except CENP-B) are associated with non-repetitive, non-alphoid DNA (Bassett et al. 2010). Since its discovery almost 20 years ago, around 100 unique neocentromeres have been described (Marshall et al. 2008). While neocentromeres often occur on the same chromosome arm (e.g. the q-arms of chromosome 3, 13, and 15), fine-mapping of centromere proteins at 3 neocentromeres on 13q32 revealed that formation of centromeric chromatin occurred on different DNA sequences (Alonso et al. 2003). The absence of true “hotspots” for binding of the centromeric histone, CENP-A, highlights the independence of centromere formation from the DNA

sequence. Neocentromeres are stably transmitted during mitosis and in some cases are even germ-line transmitted (Tyler-Smith et al. 1999). These observations led to the proposal that centromere function and propagation is not dependent on any specific DNA sequence, but instead is mediated through an epigenetic mechanism (Karpen and Allshire 1997; Vafa and Sullivan 1997; Warburton et al. 1997).

Neocentromere formation is not limited to *Homo sapiens* and has been described in a wide range of organisms. In *Candida albicans*, following the replacement of the centromere of chromosome 5 with a reporter gene, cells were able to maintain this chromosome by forming neocentromeres either distally, at loci around 200 to 450 kb away from where the reporter is located, or immediately adjacent to the insertion (Ketel et al. 2009). Similarly, in *Schizosaccharomyces pombe*, in which cen I (centromere from chromosome I) is deleted, neocentromeres have also been identified (Ishii et al. 2008). ChIP-chip analysis of the centromere proteins Mis6 and CENP-A showed that neocentromeres were frequently formed either proximal to the left or the right telomere close to, but not in contact with, subtelomeric heterochromatin (Ishii et al. 2008). Interestingly, in *Drosophila*, centromere formation can be driven by overexpression of CENP-A. These ectopic centromeres also have the propensity to form adjacent to heterochromatin domains, suggesting a role for heterochromatin in neocentromere formation (Olszak et al. 2011). However, such a role does not appear to be universally required for centromere formation as at least a subset of human neocentromeres appear to lack appreciable heterochromatin (Alonso et al. 2010).

CENP-A: A key epigenetic centromere mark

The epigenetic mode of centromere transmission finds its basis in a unique local chromatin structure. Early experiments in fission yeast addressed the behavior of reporter genes inserted within pericentromeric heterochromatin in the presence of Trichostatin A (TSA), an inhibitor of histone deacetylases. Treatment with TSA led to high levels of histone acetylation and consequently centromere silencing was alleviated and centromere function was impaired. This chromatin state at the centromere was found to be inherited throughout cell divisions, even in the absence of TSA, suggesting that the assembly of functional centromeres is at least partially imprinted in local chromatin (Ekwall et al. 1997).

In contrast to pericentromeric heterochromatin, the kinetochore-forming domain of the centromere is differentiated from the rest of the chromosome by the presence of CENP-A, a histone H3 variant that replaces the canonical histone H3 in nucleosomes at active centromeres (Palmer et al. 1991). CENP-A is a well-conserved protein that has been identified in a broad range of eukaryotes, including *S. cerevisiae* (Cse4), *S. pombe* (Cnp1), *Caenorhabditis elegans* (HCP-3), *Drosophila melanogaster* (CID), *Arabidopsis thaliana* (CENH3), *Xenopus laevis*, *Gallus gallus*, and *H. sapiens* (CENP-A). CENP-A is critical for the formation of the centromere/kinetochore complex (Foltz et al. 2006) and depletion of CENP-A, in all organisms tested so far, leads to loss of many centromere/kinetochore proteins and failure in chromosome segregation (Howman et al. 2000; Blower and Karpen 2001; Oegema et al. 2001; Régnier et al. 2005; Liu et al. 2006).

The conserved role of this histone variant and its constitutive localization at all active centromeres throughout the cell cycle make CENP-A a strong candidate for a major function in centromere specification and propagation (Allshire and Karpen 2008; Silva and Jansen 2009). Indeed, recent studies provide direct evidence that CENP-A acts as a seed that is both necessary and sufficient for the formation of a fully functional centromere (Barnhart et al. 2011; Mendiburo et al. 2011). In *Drosophila* S2 cells, tethering CENP-A^{CID}-LacI fusion protein to stably integrated LacO arrays leads to the formation of functional ectopic centromeres. Furthermore, ectopic CENP-A^{CID} was capable of assembling a functional kinetochore and direct normal CENP-A^{CID} (lacking the LacI-anchor) binding to the ectopic site (Mendiburo et al. 2011). A similar approach was used in human U2OS cells by tethering the Holliday Junction Recognizing Protein (HJURP), a CENP-A specific chaperone necessary for CENP-A assembly (Dunleavy et al. 2009; Foltz et al. 2009). In this study, LacO targeted HJURP resulted in the stable recruitment of CENP-A to the array, functional kinetochore formation and stable kinetochore–microtubule attachments (Barnhart et al. 2011). In these tethering experiments, the presence of two centromeres (the endogenous and the ectopic one) led to mitotic failure, preventing the analysis of the long-term fate of the ectopic centromere. To overcome this, Mendiburo et al. employed a plasmid-based artificial chromosome containing LacO arrays to assess the heritability of ectopic centromeres across cell divisions in *Drosophila*

S2 cells (Mendiburo et al. 2011). Normally, these plasmids undergo DNA replication but cannot segregate accurately, and are therefore lost within several cell cycles. Similar to the chromosomal LacO insertions described above, tethering CENP-A^{CID}-LacI fusion protein to the LacO arrays on those plasmids led to the recruitment of centromeric proteins and to microtubule binding. Critically, these ectopic centromeres promote stable transmission of the plasmids for multiple cell divisions, even in the absence of the fusion protein that initiated centromere formation. Together, these results provide direct evidence that CENP-A is sufficient to direct centromere formation and can initiate a self-perpetuating epigenetic feedback mechanism that controls centromere identity and stable inheritance (Fig. 2). In agreement with these findings, CENP-A nucleosomes are remarkably stable and turn over only upon replication by redistribution to the two sister chromatids (Régnier et al. 2005; Jansen et al. 2007; Hemmerich et al. 2008). Such stability provides further evidence for a key role for CENP-A in the maintenance of centromere identity.

With CENP-A taking center stage in the propagation of the centromere through an epigenetic mechanism, what then is the role of alphoid DNA in centromere formation and maintenance? While no clear role has been ascribed, it is interesting to note that inactive human alphoid arrays at chromosomally integrated sites show a variegating low level of CENP-A (Nakano et al. 2003), indicating that alphoid DNA may be a preferred substrate for CENP-A containing chromatin. This suggests that, while DNA sequence or a particular sequence context is dispensable for maintenance of CENP-A per se, alphoid DNA may facilitate centromere maintenance at multigenerational timescales.

Factors involved in cell cycle dependent assembly of CENP-A

Current evidence is consistent with a role of CENP-A in epigenetically specifying centromere identity through a chromatin-based positive feedback mechanism. This suggests that tight coordination must exist between the duplication of centromeric DNA, replication of centromeric chromatin and cell division. Interestingly, contrary to canonical histones, in human cells, CENP-A loading does not occur during S phase (Shelby et al. 2000; Jansen et al. 2007). Direct evidence for the timing of assembly of nascent CENP-A

Fig. 2 Model for the seeding and epigenetic propagation of centromeres. CENP-A is targeted to a naive LacO marked chromatin locus either by direct fusion to LacI [CENP-A^{CID} in *Drosophila* S2 cells (Mendiburo et al. 2011)] or through recruitment by the LacI-tethered chaperone HJURP [human CENP-A in U2OS cells (Barnhart et al. 2011)]. Tethering of CENP-A results in the nucleation of CENP-A chromatin. This in turn leads to functional centromere and kinetochore formation and triggers the propagation of CENP-A chromatin in a self-templating manner (likely through an adaptor intermediate) without the need for the initial LacI-seed. Once formed, CENP-A chromatin propagation and turnover through cell divisions reach an equilibrium resulting in stable inheritance of this epigenetic centromere mark

came from SNAP-based fluorescent pulse labeling experiments that allowed visualization of the newly synthesized pool of CENP-A. Despite constitutive CENP-A expression under these conditions, assembly into centromeric chromatin occurs only after exit from mitosis, in early G1 phase (Jansen et al. 2007). In agreement, measurements of steady state CENP-A across the cell cycle and photo-bleaching experiments assessing CENP-A exchange rates also established that the protein is a stable centromeric component that loads upon mitotic exit (Schuh et al. 2007; Hemmerich et al. 2008). Several factors that control the temporal loading of CENP-A have been identified to date. One of them, Mis18, was first identified in fission yeast and was shown to be required for CENP-A

localization (Hayashi et al. 2004). In humans, a complex of proteins that includes the Mis18 homologues Mis18 α and Mis18 β , as well as Mis18BP1^{HsKNL2}, is essential for CENP-A loading at the centromere (Fujita et al. 2007). Moreover, all three proteins show a similar temporal localization pattern: targeting to the centromere just prior to CENP-A assembly during anaphase and leaving around 2 to 3 h later, in mid G1 (Fujita et al. 2007; Maddox et al. 2007; Silva and Jansen 2009). Despite their critical role in CENP-A assembly, none of these proteins appear to interact directly with CENP-A (Hayashi et al. 2004; Fujita et al. 2007; Lagana et al. 2010), suggesting an indirect role for this complex. The fact that the Mis18 complex arrives prior to CENP-A assembly led to the proposal that it works as a licensing factor, perhaps by altering its surrounding chromatin environment (Fujita et al. 2007). Changing global acetylation levels by treatment of cells with TSA, a histone deacetylase inhibitor was reported to suppress a Mis18 defect, suggesting that the Mis18 complex changes local acetylation status (Fujita et al. 2007). Although this result has been disputed (Kim et al. 2012), recent work has shown that CENP-A assembly and functional centromere formation on alphoid DNA that also bears Tet operator sequences can be stimulated by local TetR-mediated tethering of Mis18 or by tethering of histone acetyl transferases (Ohzeki et al. 2012). One possible model is that the Mis18 complex includes a, yet to be defined, histone acetyl transferase that modifies local chromatin in a way that renders it permissive for CENP-A assembly.

The CENP-A specific chaperone Scm3 in fission yeast and its homologue HJURP in human cells also play a key role in CENP-A assembly (Dunleavy et al. 2009; Foltz et al. 2009; Pidoux et al. 2009; Sanchez-Pulido et al. 2009; Williams et al. 2009). HJURP co-localizes with CENP-A at centromeres during late telophase/early G1, and has the capacity to promote CENP-A chromatin assembly in vitro (Barnhart et al. 2011). This work also reported that the Mis18 complex is required for HJURP recruitment to the centromere, and that artificial tethering of HJURP to a chromosomal site is able to promote CENP-A loading in the absence of Mis18. This suggests that Mis18 functions to allow HJURP access to the centromere. However, the molecular details of such a role are still unknown. Contrary to the interaction reported between fission yeast Scm3 and Mis18 (Pidoux et al. 2009; Williams et al. 2009), in

human cells, a direct interaction between HJURP and Mis18 complex has not been described. Interestingly, the RbAp46/48 proteins have been found to interact with both the Mis18 complex and HJURP (Dunleavy et al. 2009; Lagana et al. 2010) providing a possible link between these two key CENP-A assembly factors.

Other players that participate in CENP-A assembly have been identified: Rsf-1, a member of the ATP-dependent chromatin remodeling and spacing factor (RSF) complex, and MgcRacGAP (Perpelescu et al. 2009; Lagana et al. 2010). Like the Mis18 complex and HJURP, these novel players localize at the centromere in a cell cycle dependent manner, but do so later, during mid and late G1 phase, respectively. This suggests they are involved in a different step of the CENP-A assembly process that appears drawn out over the length of G1 phase.

Mechanisms of cell cycle control of CENP-A assembly

While many of the components of the CENP-A assembly machinery have been identified, how they recognize centromeres specifically and how they are controlled in the cell cycle is unclear. Recently, we and others have made advances on this latter point. Timing of assembly of new CENP-A coincides with the conclusion of mitosis, but the mitotic signal that initiates centromere propagation remained unidentified. Previously, different models have been proposed implicating mitotic events in CENP-A assembly that include microtubule mediated forces, kinetochore formation, nuclear architecture or destruction of an inhibitor of CENP-A assembly (Mellone and Allshire 2003; Carroll and Straight 2006; Jansen et al. 2007; Allshire and Karpen 2008; Erhardt et al. 2008). SNAP-based pulse-chase labeling, which allows for the specific visualization of newly synthesized CENP-A, has been employed to demonstrate G1 phase-restricted timing of CENP-A assembly (Jansen et al. 2007). Using this methodology, we have recently dissected the mechanism of cell cycle control of CENP-A assembly and shown that timing of CENP-A loading at centromeres is controlled by cyclin-dependent kinases (Cdks) (Silva et al. 2012). Cdks are serine/threonine protein kinases that, through phosphorylation of a large number of downstream targets, are responsible for driving key steps in the cell cycle. Cdk function depends on their association with specific cyclins that confer both

activity and substrate specificity (Pagliuca et al. 2011). While Cdk levels remain relatively constant, cyclins oscillate during the cell cycle, driven by waves of cyclin gene expression and targeted protein destruction. Interphase cyclins are ubiquitinated by the Skp1/Cullin/F-box protein (SCF) complex, while mitotic cyclins are targeted for degradation by the anaphase-promoting complex/cyclosome (APC/C). This combination of Cdk phosphorylation and cyclin degradation allows for a proper sequence of cell cycle events in a unidirectional manner (Pines and Hagan 2011).

Constitutive expression of CENP-A throughout the cell cycle does not override G1 phase-restricted assembly indicating that assembly is actively prevented in S, G2, and mitotic phases of the cell cycle (Jansen et al. 2007). During these stages, the cell cycle is controlled primarily by Cdk2/cyclin A and Cdk1/cyclin B complexes. A key observation from our work has been that inhibition of Cdk activity using pan-Cdk inhibitors such as Roscovitine is sufficient to drive stable assembly of CENP-A prior to mitosis in human cells (Silva et al. 2012). These results rule out a specific involvement of mitotic events in signaling CENP-A assembly, except for the down regulation of Cdk activity during mitotic exit. Importantly, this process is independent of APC/C mediated proteolysis and protein synthesis indicating that turning on CENP-A assembly does not require synthesis or destruction of a specific CENP-A assembly activator or inhibitor, respectively. Furthermore, chicken DT40 cells carrying defined mutations in Cdk1 and Cdk2 lose cell cycle control of CENP-A assembly, leading to CENP-A loading throughout the cell cycle. Not only do these experiments corroborate the initial results using broad Cdk inhibitors, they also demonstrate that Cdk1 and Cdk2 are sufficient to maintain CENP-A assembly at bay.

CENP-A assembly factors such as HJURP or members of the Mis18 complex localize to the centromere in a cell cycle dependent fashion (Fujita et al. 2007; Maddox et al. 2007; Dunleavy et al. 2009; Foltz et al. 2009). Like CENP-A assembly, the timing of localization of these assembly factors can be manipulated by controlling Cdk activity (Silva et al. 2012). Most known CENP-A assembly factors are phosphorylated *in vivo* (Olsen et al. 2006; Dephoure et al. 2008; Wang et al. 2008; Mayya et al. 2009). Strikingly, mutations in Mis18BP1^{HsKNL2} that prevent its phosphorylation are targeted to centromere prematurely, prior to mitosis. This observation, along with the role of Cdk1 and Cdk2 in maintaining cell cycle

control, has led to a model in which temporal regulation of CENP-A assembly is achieved by Cdk-dependent phosphorylation of CENP-A assembly factor(s), preventing their localization to the centromere, consequently impeding CENP-A assembly outside G1 (Fig. 3). While Mis18BP1^{HsKNL2} has emerged as a likely target of control, additional players are possibly involved as Mis18BP1^{HsKNL2} presence at G2 phase centromeres is not sufficient to promote CENP-A assembly (Silva et al. 2012).

Conservation and differences of temporal control among eukaryotes

Loading of CENP-A homologues across different species occurs in a cell cycle regulated fashion. In *S. pombe*, using a temperature sensitive allele of a fluorescently tagged version of CENP-A^{Cnp1}, it was shown that CENP-A^{Cnp1} re-incorporation following a

shift to the permissive temperature occurs during two discrete cell cycle phases: early S and, to a lesser extent, G2 phase (Takayama et al. 2008). While interpretation of experiments based on such ts-alleles is difficult, they suggest that CENP-A is assembled primarily upon mitotic exit (that in fission yeast is immediately followed by S phase), consistent with observations in human cells. Interestingly, Scm3, a key HJURP-like factor in fission yeast, is phosphorylated at a putative Cdk consensus site (Pidoux et al. 2009). It is possible that such phosphorylation event takes place during mitosis, coinciding with loss of Scm3 from the centromere. Like fission yeast, *D. melanogaster* syncytial embryos also miss a G1 phase (Lee and Orr-Weaver 2003), and CENP-A^{CID} assembly occurs in a tight window during anaphase. As is the case in human cells, CENP-A^{CID} assembly is strictly dependent on exit from mitosis (Schuh et al. 2007). Interestingly, and in apparent contrast to the

Fig. 3 Model for cell cycle control of CENP-A assembly. Cdk1 and Cdk2 activities maintain the CENP-A assembly machinery in an inactive non-centromeric state through phosphorylation (P) of Mis18BP1^{HsKNL2} and possibly other components. Cartoon illustrates Cdk1/Cdk2-mediated inhibition of CENP-A assembly, accomplished in part through phosphorylation (P) of Mis18BP1^{HsKNL2} (member of the Mis18 complex) during S, G2 and M phases. Phosphorylation of HJURP and/or other unknown factors (symbolized by X,Y) may also be required

for this inhibition. Inhibition is alleviated through APC/C mediated destruction of cyclin B and consequent loss of Cdk1 activity in anaphase. This allows targeting of the Mis18 complex to the centromere in anaphase (licensing) followed by HJURP targeting and CENP-A assembly in G1 phase. CENP-A assembly possibly involves an exchange with H3.3 (Dunleavy et al. 2011). Canonical (H3.1 containing) nucleosomes are shown in light blue, H3.3 nucleosomes in green and CENP-A nucleosomes in red

studies described above, in *Drosophila* S2 and Kc167 cells, assembly of CENP-A^{CID} occurs in metaphase (Mellone et al. 2011). Cdk1 activity peaks in metaphase indicating that possibly, in this case, the role of Cdks in blocking CENP-A^{CID} assembly is not conserved. Another possibility is that the cyclin/Cdk complexes involved in cell cycle restricting CENP-A^{CID} assembly are different in these cells. Cyclin A is degraded in early mitosis (den Elzen and Pines 2001; Geley et al. 2001; Huang and Raff 2002) while Cdk1 activity in prometaphase and metaphase is maintained by cyclin B. Possibly, CENP-A^{CID} assembly in *Drosophila* is maintained in an inhibitory state exclusively by cyclin A driven Cdk activities during S and G2 phases, initiating the onset of CENP-A^{CID} assembly in prometaphase. Consistently, Cal1, a CENP-A^{CID} assembly factor in flies, targets to centromeres at this stage in mitosis. Furthermore, the Mellone et al. study demonstrated that CENP-A^{CID} assembly can be prevented by expression of non-degradable cyclin A. Although the cell cycle regulation of CENP-A^{CID} appears to be different between *Drosophila* cell lines and syncytial embryos, control may nevertheless be limited to Cdk-cyclin A in both systems. However, cyclin A degradation may be differentially regulated in these two cell types. In agreement with this, in *Drosophila* syncytial embryos, cyclin B is only partially degraded upon mitotic exit and is not essential for mitosis (Knoblich and Lehner 1993; Raff et al. 2002). Cyclin B is therefore an unlikely candidate to play a critical role in controlling the timing of centromere propagation. Instead, mitotic exit may be regulated primarily by loss Cdk-cyclin A activity. Cyclin A is essential for mitosis and its levels are maintained until anaphase during the initial mitotic divisions of the *D. melanogaster* syncytial embryo (Lehner and O'Farrell 1989) potentially preventing CENP-A^{CID} assembly until mitotic exit in this system. While this awaits a definitive test, these observations appear consistent with a differential role of cyclin A and B in maintaining cell cycle control of CENP-A assembly in *Drosophila*.

Cell cycle control of the CCAN

A number of proteins, commonly referred to as the constitutive centromere-associated network (CCAN) associate with CENP-A chromatin throughout the cell cycle and are considered core components maintaining

centromere structure (Foltz et al. 2006; Okada et al. 2006; Cheeseman and Desai 2008). While dependent on CENP-A chromatin for their recruitment to centromere (Liu et al. 2006), they in turn can influence assembly of nascent CENP-A. Examples of such components are CENP-H, CENP-I and CENP-K, three proteins that are present as a complex and are required to recruit newly synthesized CENP-A to centromeres (Okada et al. 2006), possibly by recruitment of the FACT1 and CHD1 chromatin modulators, that are in turn necessary for CENP-A to be properly assembled (Okada et al. 2009). CENP-N and CENP-C, also CCAN components, have been found to directly bind to CENP-A nucleosomes in vitro and play a role in the recruitment of nascent CENP-A to centromeres in vivo, placing them within the positive epigenetic feedback loop responsible for centromere propagation (Carroll et al. 2009, 2010). While to date no other component of the CCAN has displayed the G1 phase restricted assembly pattern observed for CENP-A, the assembly of several CCAN components is also under cell cycle control. CENP-I has been shown to be stable throughout the cell cycle, except during S phase where a proportion of centromeric CENP-I is turned over, possibly reflecting deposition of nascent CENP-I onto newly replicated centromeres (Hemmerich et al. 2008). In contrast, CENP-N molecules undergo rapid exchange during G1 phase of the cell cycle, at the time of CENP-A assembly, becoming stably associated to centromeres only after mid S phase (Hellwig et al. 2011), when centromeric DNA is replicated. CENP-C, another CENP-A interacting factor (Carroll et al. 2010), is also stably bound to the centromere during mitosis and S phase (Hemmerich et al. 2008). Recently, four CCAN proteins, CENP-T, CENP-W, CENP-S, and CENP-X were found to form a complex functionally and structurally resembling a histone heterotetramer that interacts with and partially wraps DNA in vitro (Nishino et al. 2012). When tethered on a naive chromatin locus, CENP-T along with CENP-C are sufficient to drive kinetochore formation (Gascoigne et al. 2011), indicating that the CENP-T-W-S-X complex, together with CENP-C, form the essential kinetochore-forming platform. Analysis of dynamics of the CENP-T/W sub complex reveals dynamics opposite to that of, e.g., CENP-N, with rapid exchange in late S phase and G2 while remaining immobile in G1 phase (Prendergast et al. 2011).

In summary, although the functional role of these divergent dynamic states across the cell cycle remains unclear, what emerges from these studies is that while the CCAN is constitutive at steady state, different components or sub-complexes display different local dynamics. These differences can be orders of magnitude apart, from immobile proteins that last days to hours (CENP-A, -I) to highly dynamic proteins such as CENP-N during G1 phase or CENP-T and -X during G2 phase that exchange on a second to minute timescale.

Importance of cell cycle control of CENP-A assembly

Despite the fact that CENP-A assembly is tightly cell cycle regulated, the biological significance for such control is still unclear. One possible explanation is that this mechanism allows for a temporal separation of centromeric chromatin assembly from general chromatin assembly. It has been shown that when CENP-A expression is limited to S phase, it is uniformly distributed throughout chromatin (Shelby et al. 1997), indicating that CENP-A can be assembled by the general chromatin assembly machinery. Limiting CENP-A assembly to outside S phase can therefore help restrict it to the centromere. In fission yeast, CENP-A assembly occurs in early S phase (Takayama et al. 2008). However, CENP-A gene synthesis precedes bulk H3 synthesis and centromeres are early replicating, potentially facilitating centromere specific deposition of CENP-A even in a system where assembly is overlapping with S phase (Castillo et al. 2007).

G1 phase assembly and subsequent centromeric DNA replication in S phase creates a condition where during mitosis the centromeres carry only half of the maximum CENP-A complement. It has been proposed (Jansen et al. 2007) and recently shown (Dunleavy et al. 2011) that histone H3 is assembled among CENP-A containing nucleosomes during S phase. It is possible that a mixture of CENP-A/H3 chromatin is important for kinetochore formation and chromosome segregation. The recent finding that CCAN components such as the CENP-T-W-S-X complex can make chromatin contacts independent of CENP-A, either directly to DNA (Gascoigne et al. 2011) or in the context of H3 chromatin (Hori et al. 2008), fuels this idea. However, whether such H3 chromatin is functionally relevant remains to be tested. In this respect it is important to note that pre-S phase assembly of

CENP-A is not universal. As in a subset of fission yeast cells, measurement of CENP-A^{CENH3} levels in plants or amoebozoia centromeres indicates a G2 phase mode of assembly (Dubin et al. 2010; Lermontova et al. 2011), inconsistent with the idea of a delicate S phase generated CENP-A/H3 balance. Nevertheless, some form of cell cycle coupling of CENP-A assembly appears to be universal, indicating the necessity for maintaining a balance between cell division and epigenetic centromere propagation. It is noteworthy that temporal control of CENP-A assembly in vertebrates by the Cdk cycle constitutes an on/off mechanisms in which the turning “on” in early G1 and “off” in late G1 may help to restrict CENP-A assembly to a narrow cell cycle window and in turn maintain centromere size.

Outlook

The recent flurry in discoveries that provide a more complete understanding on how centromeres work and how they are regulated during the cell cycle have raised many novel questions and left others unanswered. How is centromeric chromatin marked for CENP-A assembly by Mis18 complex members and how can CENP-A, once assembled survive through chromatin disruption during DNA replication? With respect to cell cycle control questions include: What is the functional role of cell cycle regulation of CCAN assembly and what is the significance of G1 phase restricted assembly of CENP-A? What are the consequences of CENP-A targeting to the centromere outside G1 phase? Moreover, despite the prominent role of Cdk activity in timing CENP-A assembly, the molecular mechanism requires further dissection. Mis18BP1^{HsKNL2} appears to be a part of this mechanism of temporal control (Silva et al. 2012) but how its activity is regulated and to which other CENP-A assembly factors this control extends are questions of great interest in future efforts.
